ABSTRACT

We present 3.6 to 70 μm *Spitzer* photometry of 154 weak-line T Tauri stars (WTTs) in the Chamaeleon, Lupus, Ophiuchus, and Taurus star formation regions, all of which are within 200 pc of the Sun. For a comparative study, we also include 33 classical T Tauri stars which are located in the same star-forming regions. *Spitzer* sensitivities allow us to robustly detect the photosphere in the IRAC bands (3.6 to 8 μm) and the 24 μm MIPS band. In the 70 μm MIPS band, we are able to detect dust emission brighter than roughly 40 times the photosphere. These observations represent the most sensitive WTTs survey in the mid- to far-infrared to date and reveal the frequency of outer disks ($r = 3\text{--}50$ AU) around WTTs. The 70 μm photometry for half the c2d WTTs sample (the on-cloud objects), which were not included in the earlier papers in this series, those of Padgett et al. and Cieza et al., are presented here for the first time. We find a disk frequency of 19% for on-cloud WTTs, but just 5% for off-cloud WTTs, similar to the value reported in the earlier works. WTTs exhibit spectral energy distributions that are quite diverse, spanning the range from optically thick to optically thin disks. Most disks become more tenuous than $L_{\text{disk}}/L_* = 2 \times 10^{-3}$ in 2 Myr and more tenuous than $L_{\text{disk}}/L_* = 5 \times 10^{-4}$ in 4 Myr.

Key words: infrared: stars – planetary systems – protoplanetary disks – stars: pre-main sequence

1. INTRODUCTION

Observational and theoretical studies are converging on the consensus that planet formation occurs in circumstellar disks within a few million years (Myr) of the central star's core formation. Beyond an age of 10 Myr, the primordial disks of dust and gas are no longer observable. The evolution of the disks during this short period when they are observable contains indispensable information about the universal prospects for planet formation. The nearest star-forming regions are over 120 pc away, and they harbor many hundreds of young stars. However, it is difficult to ascertain which stars are young cloud members and which are old field stars. Surveys for $H\alpha$ emission identified very young stars (age \sim few Myr) which are actively accreting disks. Young stars were also identified by high X-ray activity and strong lithium absorption (in late-type stars). Weak $H\alpha$ emission weak-line T Tauri stars (WTTs) are also thought to be young but their age distribution is wider than that of classical T Tauri stars (CTTs). Their modern definition on the basis of spectral properties, which is explained below, was chosen to select non-accreting young stars. They are found in very young clusters and also in older off-cloud regions (Cieza et al. 2007; Padgett et al. 2006). Thus, their evolutionary status is quite uncertain. In this paper, we will address this question in terms of the spectral energy distributions (SEDs) of WTTs

disks, and thus try to understand where WTTs fit in the larger disk evolution picture.

Current theories are trying to explain what drives the dispersal of the circumstellar gas, what halts gas accretion, in what order the different parts of the dust disk disappears, and how all these processes affect planet formation. The mechanisms proposed as pathways for disk dissipation include viscous accretion (Hartmann et al. 1998; Hueso & Guillot 2005), grain growth (Dullemond & Dominik 2005), photo-evaporation (Clarke et al. 2001; Alexander et al. 2006), and dust sweeping by companions (Lin & Papaloizou 1979; Artymowicz & Lubow 1994), among others. The general strategy for sorting out the relative importance of these mechanisms has been to observe large numbers of systems with different multiplicities, SEDs, accretion rates, and ages and to try to find correlations and trends between these measures. Early on, it was found that some WTTs had passive disks that could be detected in the submillimeter (Beckwith et al. 1990). Osterloh & Beckwith (1995) showed that WTTs had discernibly smaller millimeter wave emission than CTTs. The scheme for the identification of accreting disks based on EW($H\alpha$) went through some refinement over the years. Martín (1998) adjusted the CTTs/WTTs classification by EW($H\alpha$) according to spectral type. White & Basri (2003) suggested a further adjustment of this classification and also showed that requiring full widths at 10% height $>270 \text{ km s}^{-1}$

of the $H\alpha$ line was a much preferred way of identifying accretion disk stars (CTTSs). Further refinements and higher resolution spectra helped robustly identify stars which were weak accretors but not WTTs (Barrado y Navascués & Martín 2003; Gras-Velázquez & Ray 2005; Sicilia-Aguilar et al. 2006). Following these refinements, Andrews & Williams (2005) found that only 15% of WTTs had submillimeter emission while 91% of CTTSs were detected in the submillimeter. This signaled that most WTTs had lost the small dust grains and pebbles in their outer disks ($r > 50$ AU) where most of the dust mass in primordial disks is usually found.

Before *Spitzer*, disk surveys performed at wavelengths longward of the L band provided an incomplete picture, as cool dust disks could remain undetected in regions beyond a few tens of AUs from the stars. Haisch et al. (2001) reported on L band excess rates in clusters and clouds from 0.3 to 30 Myr, showing a well behaved decline with cluster age. Excess rates were found to be 85% at 0.3 Myr (Meyer 1996), 52% at 3.2 Myr (Palla & Stahler 2000), and only 3% at 30 Myr (Barkhatova et al. 1985). With *Spitzer*'s dramatic improvement in sensitivity in the mid- and far-infrared, the dust out to several tens of AU can be detected in the nearby star-forming regions. There have been several *Spitzer* studies for disks around young stars, and they can be categorized as: disk surveys in clusters/associations, volume-limited debris disk surveys (often age selected) and star-forming region surveys. A plethora of *Spitzer* studies on clusters and moving groups have been conducted recently. Gutermuth et al. (2007) recently reported on an Infrared Array Camera (IRAC) and Multiband Imaging Photometer (MIPS) survey of NGC 1333 ($d = 300$ pc) showing the extremely high excess rate of 83%. An IRAC study of 2–3 Myr old IC 348 cluster in the Perseus cloud yielded an excess rate of 50%, while the WTTs excess rate was found to be 36% (Lada et al. 2006; Muench et al. 2007). Surveys of several middle aged groups like NGC 2362 (5 Myr), the η Chamaeleontis association (5–9 Myr), the Upper Sco-Cen OB association (5–20 Myr), and NGC 2547 (30 Myr) have yielded excess rates from 10% to 40% (Dahm & Hillenbrand 2007; Megeath et al. 2005; Chen et al. 2005; Carpenter et al. 2006; Hernández et al. 2006; Currie et al. 2007; Gorlova et al. 2007). Excess rates for older clusters like IC 2391 (50 Myr) and the Pleiades (100 Myr) are found to be around 25% (Gorlova et al. 2006; Stauffer et al. 2005; Siegler et al. 2007), but these are due to second generation debris disks. Despite the higher sensitivities attainable for the nearby associations like the Beta Pictoris Moving Group (12 Myr) and the TW Hydra association (8 Myr), their excess rates are found to be no higher than about 35% (Rebull et al. 2008; Low et al. 2005). In studies of young (1 Myr) molecular clouds, where membership has not been established for every member by spectroscopic indicators, only the number of stars with excess can be estimated. In *Spitzer* studies of the excess populations in Ophiuchus (Padgett et al. 2008) and Lupus (Chapman et al. 2007), it was found that 10%–30% were Class III, 40%–60% Class II, and the rest were less evolved. Alcalá et al. (2008) presented a *Spitzer* study of Chamaeleon II, where they found that the cloud has similar star-forming efficiencies to Taurus and Lupus, but a disk fraction that is much higher (70%–80%) than other star-forming regions.

The debris disk surveys generally attest to the fact that second generation dust disks are common in older systems (age > 1 Gyr). In *Spitzer* studies of A stars, ranging 5–850 Myr in age, the mean excess rate is $\sim 30\%$. The maximum excess is found to be an inverse function of age, with a lifetimes of 150 Myr and 400 Myr at $24 \mu\text{m}$ and $70 \mu\text{m}$, respectively (Rieke et al.

2005; Su et al. 2006). Much lower excess rates (10%–20%) have resulted from other main-sequence surveys (Silverstone et al. 2006; Meyer et al. 2007; Trilling et al. 2008). A surprising discovery was the high rates of infrared excess around main-sequence binary stars. The observed rates were 9% at $24 \mu\text{m}$, 40% at $70 \mu\text{m}$, and almost 60% when only considering very close binaries (separation < 3 AU; Trilling et al. 2007).

One of the major goals of the *Spitzer* Cores to Disks (c2d) Legacy project (Evans et al. 2003) was to characterize the dust disks around WTTs and find their place in the planet formation picture. Thus, 187 WTTs/CTTSs in the nearest star-forming regions, Chamaeleon, Lupus, Ophiuchus, and Taurus were observed with IRAC at 3.6, 4.5, 5.8, and $8.0 \mu\text{m}$ and with MIPS at 24 and $70 \mu\text{m}$. There have already been two publications on the preliminary data from these observations. We discuss these works in the next section.

2. OBSERVATIONS

2.1. Sample Selection

The sample for this survey is well described in Padgett et al. (2006), where photometry for about half the c2d WTTs were presented. Basically, we attempted to select young stars with weak $H\alpha$ emission for which the photosphere could be robustly detected at $24 \mu\text{m}$. This meant we could only choose objects from the closer ($D < 200$ pc) star-forming clouds, Chamaeleon, Lupus, Ophiuchus, and Taurus. Young stars had been identified in these clouds by *ROSAT* detections of strong X-ray activity and by spectroscopic detections of $H\alpha$ lines with small equivalent widths (EWs; generally less than 10 \AA ; Wichmann et al. 2000; Covino et al. 1997; Wichmann et al. 1999; Martín 1998). A further selection condition was that the objects exhibit lithium absorption stronger than a Pleiades star of the same spectral type. Thus, our sample should on average be younger than the Pleiades (100 Myr). Of course, lithium is only used as a reliable indicator of youth for spectral types later than G. Almost all of our stars are of spectral types K and M.

As mentioned earlier, preliminary results from these observations have already been presented in two earlier works. Padgett et al. (2006) studied the 83 c2d WTTs that had both pointed IRAC and MIPS observations. Only a few of these deep pointed observations were inside the c2d scan maps of the five large clouds (Evans et al. 2003). The rest were off-cloud but still less than 6 deg away from the cloud boundaries in projected separation. These deeper off-cloud observations were made when the scan maps did not provide adequate sensitivity with respect to the target's photosphere. An excess rate of 6% was found for these objects. Cieza et al. (2007) collected all the known WTTs that were located within the cloud maps, adding many targets in Perseus that were not in the original c2d WTTs sample. They found that $\sim 20\%$ of the WTTs covered by the cloud maps had excess emission from dust at $24 \mu\text{m}$. Seventy micron photometry was not presented at that time. Here we present 3.6– $70 \mu\text{m}$ data on the entire c2d WTTs sample, both on-cloud and off-cloud, thus revealing the nature of dust disks around WTTs out to several tens of AU from the star. For half our sample we are sensitive to disks as tenuous as the debris disk β Pictoris ($L_{\text{disk}}/L_{*} = 2 \times 10^{-3}$), while for the other half we are only sensitive to brighter disks.

Since the publication of the first two papers in this series, we have refined the CTTS/WTTs classification criteria according to White & Basri (2003), who required a full width at 10% of

$H\alpha$ line height ($\text{FW.1H}(H\alpha)$) greater than 270 km s^{-1} (in high-resolution spectra) to classify a star as a CTTS. In the absence of high-resolution spectra, we use the $\text{EW}(H\alpha)$ to classify the objects. According to White & Basri (2003), we classify a star as CTT when $\text{EW}(H\alpha) > 3 \text{ \AA}$ for spectral types earlier than K0, when $\text{EW}(H\alpha) > 10 \text{ \AA}$ for K7-M2.5, when $\text{EW}(H\alpha) > 20 \text{ \AA}$ for M2.5-M5 and when $\text{EW}(H\alpha) > 40 \text{ \AA}$ for later types. The idea is that for an M star, stellar activity alone can produce a line width of 10 \AA (Martín 1998), whereas for earlier types the line is often saturated. We had available reduced high-resolution optical spectra (KPNO 4m, Echelle Spectra, $R \sim 42000$; Keller et al. 2003, Keller 2004) for 161 of our 187 targets. From these, we were able to measure the $\text{FW.1H}(H\alpha)$ to a precision of roughly 30 km s^{-1} . The measured line widths are presented in Table 1. Some of the targets which would have been classified as WTTSSs in the earlier papers in this series are now classified as CTTSs, and thus old results are not directly comparable. Sixteen stars, which were originally classified as WTTSS objects, are now reclassified as CTTSs. They are UX Tau, FX Tau, ZZ Tau, V710 Tau, V807 Tau, V836 Tau, Sz 41, RX J1150.4-7704, RX J1518.9-4050, Sz 65, Sz 96, RX J1608.5-3847, RX J1608.6-3922, ROX 16, SR 9, and ROX 39. Furthermore, two objects were reclassified as WTTSSs from CTTSs and they are RX J1149.8-7850 and RX J1612.3-1909.

2.2. Spitzer Photometry

In the 50 *Spitzer* hours allotted to this program (PID, 173) we observed 154 WTTSS objects and 33 CTTS. One-third of our WTTSSs were in the denser clouds regions (with $A_v > 3$), one-third were between 0 deg and 3 deg from the cloud edge ($A_v = 3$ isoline), and one-third were between 3 deg and 6 deg from the cloud edge. Given the velocity dispersion of these cloud associated sources, stars originating in the clouds should travel no farther than 6 deg in 10 Myr (Hartmann et al. 1991). We obtained *Spitzer* photometry with its IRAC (Fazio et al. 2004) and MIPS (Rieke et al. 2004) instruments. The details of the observing parameters are well-described in Padgett et al. (2006), so we will just provide the basic template here. Two 12 s exposures, plus one short 0.6 exposure in “high dynamic range” mode were taken with IRAC. These were adequate to detect the photosphere with $S/N > 50$ in the four IRAC bands centered on 3.6, 4.5, 5.8 and $8.0 \mu\text{m}$. At $24 \mu\text{m}$, we attempted to detect the photosphere, with $S/N > 20$ which resulted in integration times between 42 and 420 s. At $70 \mu\text{m}$, the photospheres are too faint to detect, and so we used the same exposure time of 360 s for all objects. This allows us to detect disks as faint as f_{lum} (or L_{disk}/L_*) = 10^{-3} for the brighter half of our sample, and disks as faint as $f_{\text{lum}} = 10^{-2}$ for the other half. Photometry were obtained from the IRAC and MIPS maps using the c2d pipeline, as described in Harvey et al. (2006), Young et al. (2005), and the c2d data delivery document.

At $70 \mu\text{m}$, aperture photometry was conducted on the filtered post-BCD (Basic Calibrated Data) images obtained from the Infrared Science Archive (IRSA; <http://irsa.ipac.caltech.edu/>). The images are super-sampled so that the pixels are of size $4''$ instead of the original $10''$. The aperture centers were fixed using the astrometry information in the FITS file headers. We used an aperture of radius $16''$ and a sky annulus with inner and outer radii of $18''$ and $39''$, for which an aperture correction factor of 2.07 is recommended (MIPS data handbook, updated 2009 October). The IDL routine *APER.PRO* was used to perform the photometry and estimate the uncertainties which are obtained from the pixel-to-pixel noise in the sky annulus. Detections

with signal-to-noise ratio (S/N) above 3 are initially considered real, but subsequently checked for shape, confusion with nearby, sources, and nearby nebulosity. Upper limits of 3σ , for sources not detected at $70 \mu\text{m}$, are given in Table 2. The absolute calibration uncertainty for $70 \mu\text{m}$ is 15% (Gordon et al. 2007). This error is added in quadrature to the photometric uncertainty. We note that the $70 \mu\text{m}$ fluxes presented in this paper are larger by a factor of ~ 2 than those reported in Padgett et al. (2006), as the earlier photometry was done before aperture radii and correction factors were properly calibrated and standardized by the Spitzer Science Center (<http://ssc.spitzer.caltech.edu/mips/>).

Because of the significantly lower imaging resolution at $70 \mu\text{m}$, it is much more difficult to decide which detections are bona fide, compared to the other bands. This is especially true when the S/N of the detections are below 10, or when there is neighboring nebulosity. We consider any detected $70 \mu\text{m}$ emission to be associated with the target star with high confidence when the separation of the center of emission and the star as seen in the IRAC bands is less than $\text{FWHM}_{70}/(S/N)_{70}$. Thus, for a $70 \mu\text{m}$ detection with an S/N of 3, the separation between the emission centers must be less than $16''/3 \sim 5''.3$. When the separation is larger than this limit, but less than the nominal FWHM at $70 \mu\text{m}$ ($16''$), we check in the IRAC images to see if the $70 \mu\text{m}$ emission center is better matched by any other source. If there is no better match, and the surrounding nebulosity at $24 \mu\text{m}$ and $70 \mu\text{m}$ can be ruled out as sources of confusion, then the emission is still assumed to be coming from the target star. Where the $70 \mu\text{m}$ detections suffer from confusion, it is possible that the $24 \mu\text{m}$ photometry, as given in the IRSA catalogs, are also contaminated. For these targets, the $24 \mu\text{m}$ aperture photometry was repeated (replacing the IRSA catalog values) according to the MIPS data handbook recommendations for an aperture radius of $7''$. This resulted in new photometry for the WTTSS sources RX J1607.2-3839, RX J1608.3-3843, and RX J1609.7-3854.

In Figure 1, we show all the WTTSS $70 \mu\text{m}$ detections which we consider to be bona fide. Overlaid in the figure are contours from *Spitzer* maps in the 3.6, 8, and $24 \mu\text{m}$ bands. When a nearby source was detected close to the target aperture, it was subtracted using a custom IDL routine. This routine takes the centers of nearby sources and removes the median flux in annuli around this center. Adjacent sources were removed in the case of HBC 423, HBC 422, DI TAU, HV TAU, and RX J0445.8+1556 (see Figure 1). A bar-like artifact also had to be removed in the case of ROXS 43A. In some cases, the spurious detection is entirely due to a known source close to the target. We discuss these cases below. The flux detected in the DoAr 21 aperture probably originates from the bright H II region FG Oph 17 which reaches within $4''$ of the target. In the *Spitzer* 8 and $24 \mu\text{m}$ images, we also see the surrounding nebulosity getting stronger at longer wavelengths. The $70 \mu\text{m}$ emission is also highly irregular in shape and it is difficult to claim with confidence that it results from disk emission. Jensen et al. (2009) detected polycyclic aromatic hydrocarbon (PAH) emission in an irregular distribution over hundreds of AU from the star but could not ascertain if there was any emission coming from a circumstellar disk. In the case of HV Tau, the $70 \mu\text{m}$ emission is actually coming from HV Tau C (Stapelfeldt et al. 2003), which is an edge-on disk that lies $4''$ to NE of the target (the AB component). There is a very bright YSO, 2MASS J16272146-2441430, contaminating the field and causing a spurious detection for ROX 21. The RX J0445.8+1556 detection was because of contamination

Notes. FW.1H: notes of the full width at 10% of H alpha line. (Keller 2004; 0* indicates non detections). Negative velocities indicate absorption. Bin. notes: the separation of binary component is arcseconds or their period in days. Limits on non detection are also given; e.g., <0.13 indicates a companion is only possible for $\rho < 0''.13$. Binary references: 1. Leinert et al. 1993, 2. Simon et al. 1995, 3. Lafrenière et al. 2008, 4. Prato 2007, 5. Ratzka et al. 2005, 6. Köhler 2001, 7. Guenther et al. 2007, 8. Köhler & Leinert 1998, 9. Negative numbers indicate that objects are within cloud boundary as defined in the text.

Notes. The absolute calibration uncertainties in the IRAC bands and the MIPS-24 μ m band are 5% and 10%, respectively. These calibration uncertainties are typically more than twice the random errors and thus dominate the total photometric uncertainty.

from the nearby star, GSC 01267-00433. For RX J0842.4-8345, the 70 μ m flux clearly originates from a separate nearby source which appears clearly resolved at 8 μ m. In the case of

RX J1129.2-7546, there is confusion from a known nearby source 8' to the East (2M J11291470-7546256; Luhman et al. 2008), which appears at 3.6 μ m and begins to dominate at

Figure 1. 70 μm images of the detected WTTs targets. North is up and East is left. Contour map overlays from the IRAC1, IRAC4, MIPS-24 μm and MIPS-70 μm bands are shown in blue, green, pink, and orange, respectively. The contour levels shown are at 3, 15, 75, and 375 times the background root mean square. The red circles represent the 16'' (radius) object aperture and the 39'' outer sky aperture used for photometry. The 18'' inner sky aperture is not shown.

(A color version of this figure is available in the online journal.)

24 μm . False detection of RX J1301.0-7654 was also caused by the nearby YSO, 2MASS J13005323-7654151. Near WA Oph1, a faint resolved 24 μm source appears 8'' to the North, and although its location does not match well with the 70 μm emission, it is a better match to the emission than our target. A similar situation arises in the case of RX J1612.0-1906A. For RX J1621.2-2342a, RX J1623.8-2341, ROX16 and SR9, it is clear that there is too much nearby nebulosity to be confident that 70 μm detections are associated with circumstellar disks. In some cases, the nebulosity is already seen at 8 and 24 μm and gets stronger at longer wavelengths. Photometry at 70 μm was not obtained for NTTS 043230+1746 and RX J1159.7-7601, as the c2d *Spitzer* observations had the wrong pointings for these objects.

3. RESULTS

3.1. Estimating Infrared Excess

Targets with redder colors than main-sequence stars imply emission due to warm dust. The warmer the dust, the shorter the wavelength at which the excess is observed. As in the previous c2d papers on WTTs (Padgett et al. 2006), we look for color excess using the 2MASS and *Spitzer* bands. First, we look at $K-[24]$ colors, since the MIPS-24 μm band is our most sensitive band to typical circumstellar dust emission.

The stellar K -band magnitudes have to be corrected for extinction before we calculate $K-[24]$ colors since many of our targets are embedded in their parent star-forming clouds. We use $A_V = 5.88E(J-K)$ to estimate the extinction for our sources, where $E(J-K)$ is the excess in $J-K$ color with respect to the expected stellar photosphere. The main-sequence $J-K$ colors are from Kenyon & Hartmann (1995). Extinction corrections were made according to Indebetouw et al. (2005), who based their empirical law on IRAC data from the GLIMPSE (Galactic Legacy Infrared Mid-Plane Survey Extraordinaire) project. The law is recommended for 2MASS and IRAC bands and relates

Table 3
Relative Extinction in Optical, 2MASS, and *Spitzer* Bands

Band	V	J	H	K	IRAC1	IRAC2	IRAC3	IRAC4
A_λ/A_K	8.8	2.5	1.54	1.0	0.57	0.44	0.41	0.37

A_λ to A_K as shown in Table 3. The derived extinctions A_V are displayed in Table 1. Extinction in the K band is below 0.2 mag for most our objects but some have very high extinctions. Thus, corrections to the $K-[24]$ colors were applied, even though adding extinction correction introduces noise into the $K-[24]$ color estimates, thus reducing our sensitivity to photospheric excess. There are 49 sources with $A_V > 2$ in our sample. We note that other than foreground cloud material, extinction could also result from occultation by an optically thick circumstellar disk.

While the photospheric $K-[24]$ color for A to G dwarfs is almost zero, it can be up to 1 mag for an M dwarf, thus it is important to subtract the intrinsic photospheric colors before determining excess. The estimated $K-[24]$ colors for the photosphere were taken from Gautier et al. (2007). The photospheric colors $K-L$, $K-M$ and $K-N$ were also available from Kenyon & Hartmann (1995), and these were used for color corrections in the IRAC bands. Now, even though the exposure times were enough to robustly detect the photosphere at 24 μm , 6 of our 154 WTTs are close to the confusion limit. To estimate the excess in the 24 μm band, we select the objects brighter than 0.5 mJy at 24 μm , a flux level at which we are assured negligible spurious detections and better than 95% completeness (Papovich et al. 2004). We end up with 148 WTTs and 33 CTTs with reliable $K-[24]$ colors. The rejected objects were RX J0439.4+3332a, RX J1123.2-7924, RX J1614.2-1938, RX J1614.4-1857a, and RX J1615.1-1851.

After subtracting the photospheric colors, we get a robust median (rejecting outliers) of 0.03 mag for the $K-[24]$ colors,

Figure 2. Left: $EW(H\alpha)$ vs. the excess $K-[24]$ color for our sample of 181 stars. 148 WTTSSs are shown as circles. 33 CTTSs are shown as squares. The $EW(H\alpha)$ come from low-resolution spectra, but the CTTS classification is adjusted using $FW.1H(H\alpha)$ estimated from high-resolution spectra. The dashed line shows the median color for the objects without excess. The dotted line is the 3σ marker for excess identification. A negligible offset has been added to the $EW(H\alpha)$ values to allow easier plotting. Right: a histogram of $K-[24]$ excess for just the WTTSSs. The solid red curve is a Gaussian with mean at $K-[24] = 0.02$ mag, and 1σ dispersion of 0.15 mag. The blue dotted line histogram is just a coarser binning of the same distribution. (Caution: it extends beyond the plot boundary at the peak of the distribution). (A color version of this figure is available in the online journal.)

and a robust standard deviation of 0.15 mag. Throughout this paper, we identify the sources with excess color by looking at the color distribution itself. This method has been demonstrated in earlier *Spitzer* papers (Su et al. 2006; Padgett et al. 2006; Cieza et al. 2007). Most of our sources exhibit bare photospheres and should have zero excess colors. This group manifests itself as a Gaussian distribution with zero mean and some dispersion. The sources that lie 3σ away from the mean are the ones we identify as excess sources (see Figure 2, right). This criteria yields $16 (11\% \pm 3\%)$ objects with a 3σ detection ($K-[24] > 0.45$ mag) of excess at $24 \mu\text{m}$.

We plot the $H\alpha$ EWs versus the excess $K-[24]$ colors in Figure 2. It is clear from Figure 2 that the WTT excess objects do not all lie near some WTTSS/CTTS boundary, and the vast majority of these objects have $EW(H\alpha)$ much lower than 10 \AA . Almost all (30 out of 33) CTTSs show $24 \mu\text{m}$ excess. The exceptions are RX J1150.4-7704, RX J1518.9-4050, and ROX 39. The first two stars would have been WTTSSs according to the low-resolution $EW(H\alpha)$ but are classified as CTTSs because of large $H\alpha$ widths seen in high-resolution spectra. ROX 39 is a K5 star with $EW(H\alpha) = 3.6 \text{ \AA}$ which is near the WTTSSs boundary. Thus, they are relatively weak accretors.

In Figure 3, we plot the $[3.6]-[24]$ color excess against the $K-[24]$ color excess (or $EX(K-[24])$) for the sources that had detections in the involved bands. We note a high degree of correlation between the two excesses and infer that these two measures are consistent with each other. All of the 148 WTTSSs with reliable $K-[24]$ colors also have IRAC1 photometry. Of these, 16 ($11\% \pm 3\%$) had excess detection above the 3σ level, the same as our estimate from $K-[24]$ colors. However, one of the candidate sources from the $K-[24]$ excess objects is not found to be a $[3.6]-[24]$ excess source, and vice versa. This discrepancy is likely due to the fact that there is excess in the IRAC1 band itself. It is easy to see from Figure 3 that the WTTSS color excesses have a much wider distribution than the CTTS excesses. Counting only the excess objects, the fraction of CTTS

Figure 3. Excess $[3.6]-[24]$ vs. $K-[24]$ colors for our sample. WTTSSs are shown as filled circles. CTTSs are shown as squares. The dashed lines are the 3σ markers for excess identification.

(A color version of this figure is available in the online journal.)

with $EX(K-[24]) < 2.5$ mag is only 6.7% (2/30). However, $44\% \pm 16\%$ (7/16) WTTSSs excess sources fall in this range. Thus, roughly half of the excess WTTSSs fall between CTTSs and diskless stars, in terms of $24 \mu\text{m}$ excess.

3.1.1. Disk “Turn-on” Wavelengths and Disk Holes

Excess in a particular band indicates the presence of circumstellar dust with temperatures in a certain range. Consideration

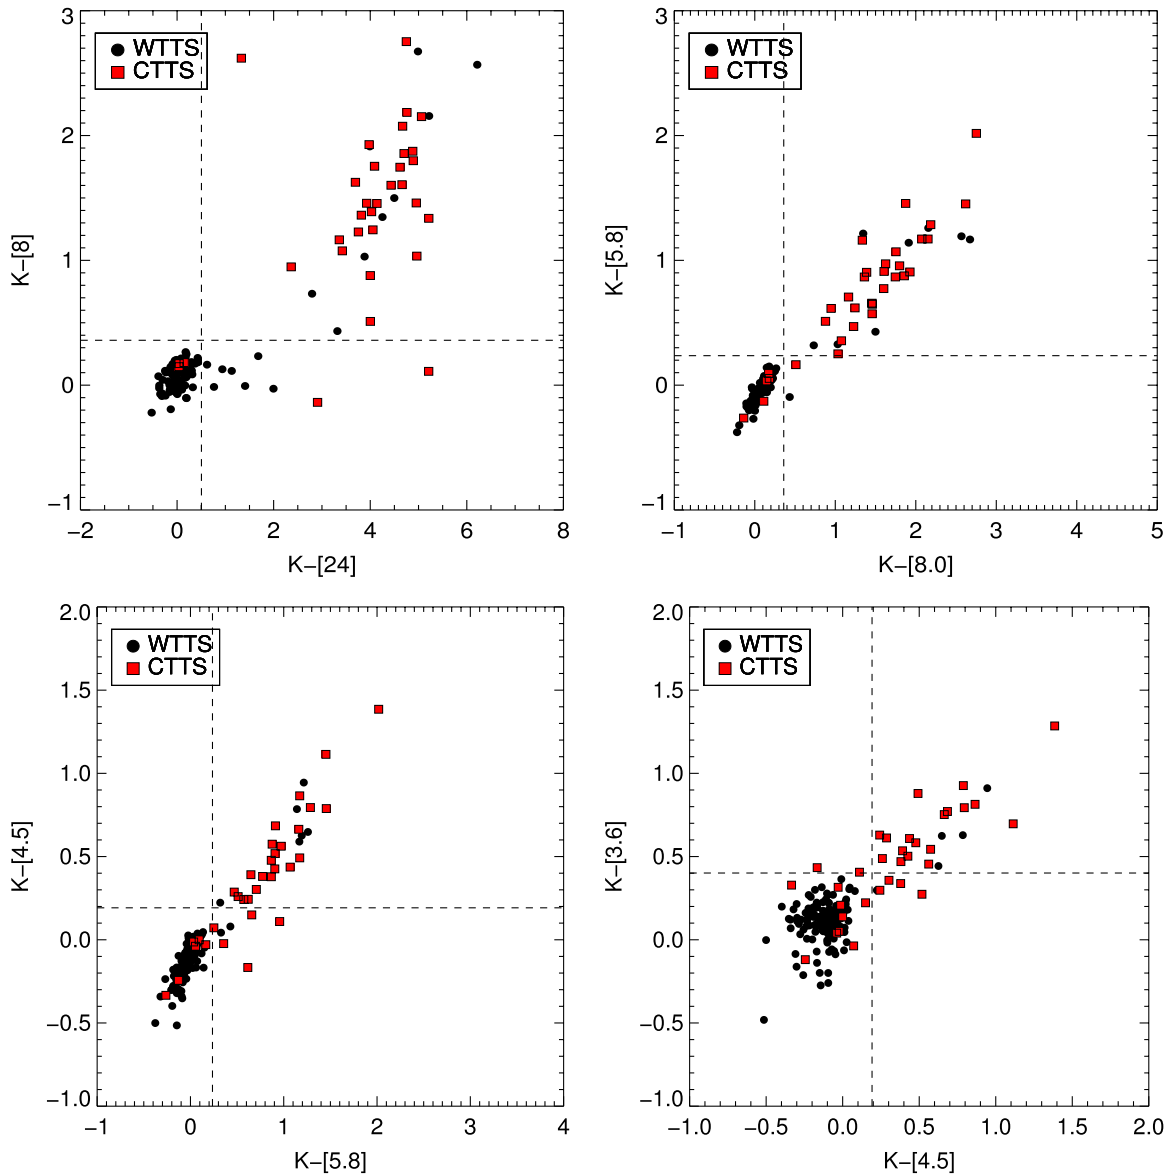

Figure 4. WTTS and CTTS symbols are the same as before. We plot the excess $K-[X]$ color in adjacent bands against each other, revealing the shortest wavelength band at which the disk emission first “turns on.” Here $[X]$ represents the wavelength of the *Spitzer* band. The dashed lines represent the 3σ markers for excess identification.

(A color version of this figure is available in the online journal.)

of the frequency form of Wien’s displacement law suggests that these temperatures are roughly 40 K, 120 K, 350 K, 480 K, 620 K, and 780 K for the 70, 24, 8, 5.8, 4.5, and $3.6\ \mu\text{m}$ bands, respectively. For the median stellar luminosity of our sample, $0.5 L_{\odot}$, we estimate that these temperatures are reached by circumstellar dust at orbital radii of 100, 10, 1.3, 0.7, 0.4, and 0.25 AU, respectively. When infrared excess in a particular band is accompanied by the lack of excess at shorter wavelengths, an inner cleared region or hole in the circumstellar disk is indicated. We plot the excess in adjacent *Spitzer* bands against each other, in Figure 4, in order to identify the disks with inner holes. We also try to identify the shortest wavelength at which the disk emission first “turns on,” i.e., appears above detection limits, as we trace the excess from short to long wavelengths. In the same sense, the disks “turn off” as we go from long to short wavelengths, when their excess emission becomes too small to be detectable.

In the top-right panel of Figure 4, we plot the excess $K-[8.0]$ colors against the $K-[24]$ colors of our sample. There are 7 WTTSs with $24\ \mu\text{m}$ excess that lack $8\ \mu\text{m}$ excess. Thus, 10 disks “turn on” at $24\ \mu\text{m}$, another one turns on at $8\ \mu\text{m}$, 2 more turn on at $5.8\ \mu\text{m}$, and 2 more turn on at $4.5\ \mu\text{m}$, leaving 4 WTTSs which were already turned on at $3.6\ \mu\text{m}$ and possibly also have excess in the K band. We designate these objects according to their disk “turn-on” wavelengths. Thus, we have 7 **T24** (turns on at $24\ \mu\text{m}$) objects, 5 **TIRAC** objects (turns on at IRAC wavelengths), and 4 **TNIR** objects (already show excess at IRAC1 and could have K band excess). We will use these designations to describe the SEDs of the objects throughout the paper, and later connect these to plausible physical interpretations of the evolutionary states of the disks. CTTS disks also turn off at IRAC wavelengths, but in fewer numbers than WTTSs. Only one-third of CTTS disks turn off in one of the observed bands, whereas nearly 80% of WTTS disks are observed to turn off.

Figure 5. $K-[70]$ excess color vs. $K-[24]$ excess color for our sample. The dashed line is the 3σ marker for $24\mu\text{m}$ excess identification. (A color version of this figure is available in the online journal.)

In Figure 5, we compare infrared excesses at 24 and $70\mu\text{m}$. We see that the $70\mu\text{m}$ excess has to be roughly 40 times (i.e., 4 mag) greater than the photosphere to be detected. The 3σ $70\mu\text{m}$ sensitivity for our survey is roughly 10 mJy (see Table 2). We detect 8 WTTSSs and 27 CTTSs at $70\mu\text{m}$ and all of these are detections of excess at least 3.5 mag brighter than the photosphere. Our $70\mu\text{m}$ excess detection rate for WTTSSs is $5\% \pm 2\%$, while for CTTSs it is $82\% \pm 16\%$. We find only 1 WTTSS with $70\mu\text{m}$ excess for which we detect no $24\mu\text{m}$ excess. This hardly changes the overall excess rate for WTTSSs of $11\% \pm 3\%$ (17 of 148). This WTTSS is HBC 422, a companion to another WTTSS, about $35''$ away, HBC 423 which itself has a $70\mu\text{m}$ excess. If the excess is truly associated with the star, then this indicates cool dust in orbit relatively far from the star (~ 50 AU). To keep track of the SED designations we call this a **T70** object since its excess turns on at $70\mu\text{m}$. The disk is very likely optically thin. None of the CTT SEDs show evidence of such large inner holes.

In summary, while $\sim 89\%$ of WTTSSs are diskless, the rest have a rich variety of SEDs, indicating a wide range of evolutionary states. If circumstellar disks progressively clear from the inside out, the SED types ordered from least to most evolved would be **TNIR**, **TIRAC**, **T24**, and **T70**. We designate diskless objects as **RJ** indicating that their SEDs have a Rayleigh–Jeans slope longward of the K band.

3.2. Properties of On-cloud and Off-cloud Sources

The discrepancy in the WTTSS excess fractions found in the earlier papers in this series ($\sim 20\%$ in Cieza et al. 2007 and $\sim 6\%$ in Padgett et al. 2006) strongly suggested that the distance from the cloud may be an important factor affecting the excess rate. It is likely that WTTSSs with larger separations from the clouds include a much older population of stars than the ones close to the clouds. To investigate this connection, we attempted to find the projected separations of our sample from their parent clouds in a systematic manner. We defined the cloud edge as the $A_V = 3$ contour line. However, extinction maps produced in the

same fashion for all the clouds were not available, especially not for regions a few degrees away from clouds. Thus, we decided to use the dust temperature derived all-sky extinction maps created by Schlegel et al. (1998). These maps were created from COBE/DIRBE and IRAS/ISSA maps and have the calibration quality of the former with the spatial resolution of the latter. The maps show a great deal of filamentary structure and trace the H I maps well but are less reliable in regions where H I is saturated. In comparison to more ideally produced extinction maps, as in Cambr esy (1999), we find that the agreement of the contour lines are at the $10'$ level. We should note that, while in cold regions these maps may give reliable extinctions, where there is heating by nearby hot stars as in the case of Ophiuchus, the maps become suspect. From the analysis that follows, however, we will see that we have sufficient accuracy to obtain meaningful results.

Plotting the projected distances (r_c) of the WTTSSs estimated from these extinction maps against their $K-[24]$ excess colors, we find that of the 70 WTTSSs within 1° of their parent cloud, 13 ($19\% \pm 5\%$) have disks (Figure 6). Regions within 1° of the cloud edge will be called “on-cloud” hereafter. The excess rate for the 78 WTTSSs that lie farther away is $5\% \pm 3\%$, i.e., 4 WTTSS disks are clearly off-cloud. Given the significant discrepancy between on-cloud and off-cloud excess rates, it seems likely that the off-cloud WTTSSs are a physically different group of objects, perhaps older. Moreover, we should remember that the 70 WTTSSs which are projected within 1° of the clouds still have some foreground off-cloud objects, so the actual on-cloud excess rate could be much higher than we estimate here.

In the right panel of Figure 6, we display the $K-[24]$ excess colors of each of our targeted WTTSS clouds separately. We find excess fractions of $8\% \pm 6\%$, $7\% \pm 4\%$, $19\% \pm 7\%$, and $11\% \pm 5\%$ for the Chamaeleon, Lupus, Ophiuchus, and Taurus regions, respectively. In terms of the distribution of the different kinds of WTTSS disks, all the clouds are quite similar, although we should note it is difficult to draw distinctions from so few detections. Only Ophiuchus has a notably higher WTTSS disk fraction, while the rest of the clouds have virtually indistinguishable fractions given the large uncertainties. An offset proportional to the projected separation of WTTSSs from their parent clouds has been added to the x-axis values in Figure 6 (right). We note that the off-cloud WTTSSs objects with excess are two **TNIR** disks near Chamaeleon and two **T24** disks near Lupus.

The WTTSSs with excess in Taurus and Ophiuchus are all within 1° of their cloud edge, while all the Chamaeleon excess sources lie off-cloud (Figure 8). In the literature the mean ages for Taurus and Ophiuchus are often found to be younger than the other two clouds (Allers et al. 2007).

In Figure 7, the A_V s derived from $J-K$ colors are plotted against the projected distances from the respective clouds. Apart from one clear outlier (T Cha, an optically thick disk) with an $A_V \sim 10$, roughly 1.5 deg from the cloud edge, we see that all high A_V objects lie within 1° of the cloud edge and the highest A_V sources lie well within. T Cha is thought to have a close to edge-on disk (Alcala et al. 1993; Brown et al. 2007) and so in this case the high extinction is probably caused by disk occultation. Almost all the other off cloud sources have low extinctions. This suggests that both A_V and distance from cloud edge has been derived with high fidelity and, moreover, the high A_V sources are very likely embedded in the clouds, and thus real cloud members. The excess rate for WTTSSs with $A_V > 1$ is 11 out of 41 ($27\% \pm 8\%$). Objects with less than zero projected cloud separations (these are within the cloud boundaries) have

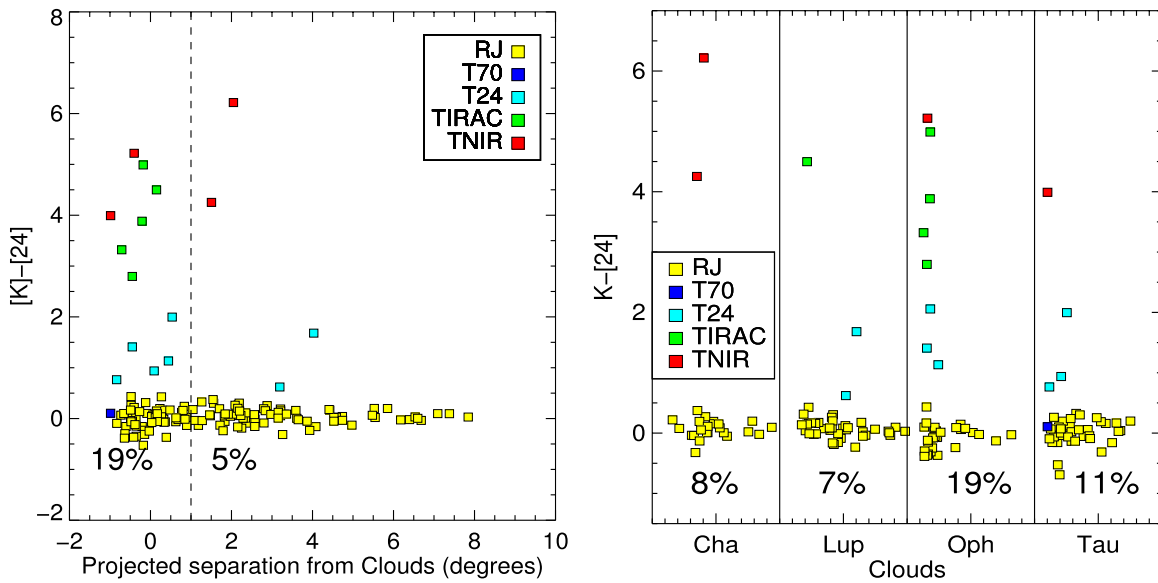

Figure 6. Left: excess $K-[24]$ color vs. distance from cloud edge in degrees. Objects are colored according to their disk “turn-on” wavelengths. **RJ** indicates diskless objects. The dashed line is the 1° from cloud edge demarcation. The excess fractions on either side of this boundary is given at the bottom of the plot. Right: the excess $K-[24]$ color of the WTTs shown for each cloud separately. A small offset proportional to the projected separation from the parent cloud has been added in the horizontal direction for ease of viewing.

(A color version of this figure is available in the online journal.)

Figure 7. A_V derived from $J - K$ color plotted against projected distance from cloud edge. Negative projected distances indicate objects inside the clouds. Objects are colored according to SED types and are given symbols according to parent cloud region. As expected almost all high extinction objects are on-cloud, while almost all off-cloud objects have low extinctions.

(A color version of this figure is available in the online journal.)

extinctions spanning the entire range starting from zero. Thus, these objects constitute both foreground and cloud-embedded objects.

Since the on-cloud WTTs are a younger population with much lower contamination by older objects, we investigate the excess rate of these objects with respect to spectral type. In Figure 8, we plot the histogram of the spectral types of WTTs with $r_c < 1^\circ$ with and without disks. We leave out a few very early type objects because of very low number statistics at that

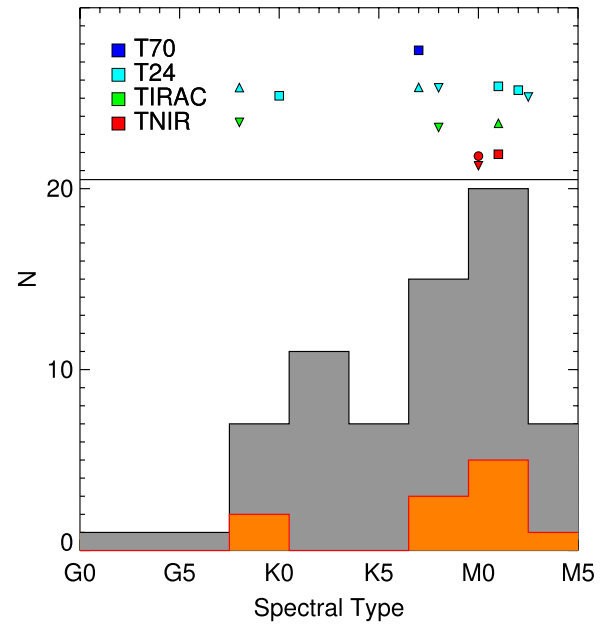

Figure 8. Histogram of the spectral types of WTTs with $r_c < 1^\circ$ is shown in gray. The histogram of the subset with disks is shown in orange. A very small minority of WTTs with spectral types earlier than G0 are not shown. Also overlaid on this plot are the symbols representing the types of the individual WTTs disks. The shapes of the symbols represent different clouds, same as in Figure 7. The excess rate for WTTs between G0 and K5 is $2/20$ ($10\% \pm 7\%$), while the excess rate for WTTs between K6 and M5 is $9/46$ ($20\% \pm 7\%$). The significance of the difference in these rates is only about 1σ .

(A color version of this figure is available in the online journal.)

end. The excess rate for spectral types G0 through K5 was 2 of 20 ($10\% \pm 7\%$), while the excess rate for spectral types K6 through M5 was 9 of 46 ($19\% \pm 7\%$). The later spectral types seem to have a higher excess rate, but the result is only 1σ significant. However, we see from the disk type designations of the WTTs in Figure 8 that the less evolved SEDs seems to be concentrated in the later spectral types.

Figure 9. Filled histogram shows the distribution of the measured fractional luminosities (f_{lum}) for our WTTSS. The unfilled histogram shows the distribution of the upper limits to f_{lum} s for the WTTSS without detections of infrared excess.

4. DISCUSSION

4.1. Disk Fractional Luminosities

The fractional luminosities of disks ($f_{\text{lum}} = L_{\text{disk}}/L_{\star}$) provide a model independent measure of the dust contents of the circumstellar environments. It is also a convenient way to characterize the rich variety of SEDs found around WTTSS by a single number, which is expected to have some connection to their evolutionary status. We compute the fractional luminosities in the following way. We consider only the photometry and upper limits in the IRAC and MIPS bands, since excesses were only computable past the K band. The appropriate photospheric fluxes are subtracted from the *Spitzer* photometry of each star, assuming that the K band fluxes come solely from the photosphere. The flux densities are integrated according to Simpson’s rule from the K band through $70\ \mu\text{m}$. The stellar flux density is similarly integrated from $0.01\ \mu\text{m}$ to $100\ \mu\text{m}$ assuming a blackbody spectrum with the star’s temperature, normalized to the K band flux. Thus, f_{lum} is computed by taking the ratio of these two integrals.

However, most of the time, we have only a $70\ \mu\text{m}$ upper limit and/or no $24\ \mu\text{m}$ detection of excess. Thus, there are three cases which we treat separately. For case 1, when we have detections of excess in both MIPS bands, we compute the minimum f_{lum} . Past $70\ \mu\text{m}$, we assume a modified blackbody ($T = 40\ \text{K}$) where the flux density behaves as $f_{\nu} \sim \lambda^{-3}$, instead of $f_{\nu} \sim \lambda^{-2}$ (Rayleigh–Jeans slope). For case 2, when we have a $24\ \mu\text{m}$ excess detection but only a $70\ \mu\text{m}$ upper limit, we use a modified blackbody ($T = 150\ \text{K}$) past $24\ \mu\text{m}$. In a few cases where the modified blackbody extrapolates to fluxes above the $70\ \mu\text{m}$ upper limit, the upper limit is adopted as the flux estimate and used as the starting extrapolation point for the modified blackbody. Thus for case 2, we are also computing minimum f_{lum} . For case 3, we have no detections of excess in any of the bands, thus we can only compute an upper limit to the f_{lum} . This is done by adopting a modified blackbody, which passes through both 24 and $70\ \mu\text{m}$ upper limits. Our estimates for the disk f_{lum} are given in Table 1. It seems that the median sensitivity limit for the WTTSS sample is $f_{\text{lum}} < 5 \times 10^{-4}$. We also note that we are not sensitive to disks cooler than $40\ \text{K}$.

Figure 10. H-R diagram for our sample of stars with the Siess et al. (2000) evolutionary tracks. The solid blue lines are isochrones for 1, 5, 10, and 100 Myr. The 100 Myr line basically coincides with the main-sequence track (not shown here). The solid red lines represent mass tracks for 0.1 , 0.5 , and $1.0 M_{\odot}$, as labeled in the figure.

(A color version of this figure is available in the online journal.)

Most of the detected disks have f_{lum} ranging from 5×10^{-2} to 5×10^{-4} , although there are disks which are as tenuous as $f_{\text{lum}} \sim 1 \times 10^{-5}$. A histogram of the measured f_{lum} is shown in Figure 9.

The most robust debris disks have $f_{\text{lum}} < 1 \times 10^{-2}$ (HR 4796A, β Pictoris). We have nine WTTSS with smaller f_{lum} , making them the youngest debris disk candidates. However, we do not know whether these excess emissions results from remnants of primordial disks or second generation disks created by collisional grinding of planetesimals. Only two of these nine debris disk candidates lie beyond 1° of the cloud edge. Moreover, the robust mean age (explained in the next section) of the 9 WTTSS is $1.5 \pm 0.4\ \text{Myr}$, with a spread of $1.2\ \text{Myr}$, which makes them as young as the on-cloud WTTSS population. Seven of these are **T24** objects, one is a **T70**, and the other one is a **TIRAC** object. Thus, as expected, lower f_{lum} correlate very well with long “turn-on” wavelengths.

4.2. Age Analysis

It is interesting to compare the ages of the WTTSS to the evolutionary states inferred from their disk SEDs. Age analysis is always a difficult task since evolutionary tracks are often extremely close together on the Hertzsprung–Russell (H-R) diagram. According to the stellar evolutionary tracks of Siess et al. (2000), all the mass tracks are in a very narrow temperature range at $1\ \text{Myr}$ (3000 – $4500\ \text{K}$; see Figure 10). For our sample, we have an additional difficulty in estimating ages. The distances to the individual objects, especially the ones located outside the clouds, are not known precisely and should be assumed to be uncertain by $\sim 20\%$. This introduces a 40% uncertainty into the intrinsic luminosity of the object, dominating any calibration or bolometric correction uncertainty in the age determination. Moreover, there is the uncertainty in temperature which is

assumed to be a spectral subtype. However, these problems are somewhat mitigated by the fact that, for low mass stars, luminosities can decrease by a factor of 6 as the star ages from 1 to 10 Myr. Moreover, when analyzing the properties of an ensemble, the median ages of the various classes of objects are less disturbed than the individual ages due to the present uncertainties. Large variations in the mean ages of two classes of objects may still be discernible.

As shown by Cieza et al. (2007), even though absolute ages can vary significantly depending on which evolutionary models are used, the relative ages between objects are quite reliable. Our age estimates, all of which come from the Siess et al. (2000) models, should only be used to compare the relative ages of groups of objects.

We assume that each star in our sample is at the distance of their parent cloud which we take from the literature: 180 pc for Chamaeleon II, 200 pc for Lupus, 125 pc for Ophiuchus, and 145 pc for Taurus (de Geus et al. 1989; Whittet et al. 1997; Wichmann et al. 1998; Comerón 2008). These distances are used to obtain the absolute K magnitudes from the extinction corrected apparent K magnitudes. The intrinsic luminosities were computed from bolometric corrections applied to the absolute K magnitudes. Bolometric corrections to the K magnitudes were derived from a table presented in Kenyon & Hartmann (1995). The intrinsic luminosities and the stellar spectral types are then used to estimate the stellar ages, using the Siess et al. (2000) evolutionary models. In Figure 10, we place our objects on an H-R diagram. The error bars in the intrinsic luminosities and the temperatures discussed above are not shown in the figure. Plotting these large error bars on an already complex plot would only serve to muddle the subtle separations between different groups of objects.

In the following analysis, we quote the robust means of the ages of various groups of stars. This quantity is measured by taking the median and the robust sigma of a group of objects. The robust sigma is calculated using the IDL routine, *robust_sigma.pro*. All values that lie 3σ (robust) away from the median are rejected. The mean of the rest of the values is then calculated along with the uncertainty in this mean. The percentage of rejected values is never more than 20%.

The first thing to notice in Figure 10, is that most CTTSs are younger than 1 Myr (61% or 20/33). All of them are younger than 10 Myr, with just one exception. For the WTTSs, only 16% (22/148) are younger than 1 Myr. For the WTTSs younger than 1 Myr, $41\% \pm 14\%$ (9/22) have disks, while only $6\% \pm 2\%$ (8/126) WTTSs older than 1 Myr have disks. We can also look at the robust mean ages of CTTSs, WTTSs with disks, and WTTSs without disks which are 0.8 ± 0.1 , 1.3 ± 0.3 , and 3.7 ± 0.3 Myr, respectively.

There is a strong trend in overall excess fraction with age. In the three age bins, $t < 1$ Myr, $5 \text{ Myr} > t > 1$ Myr, and $t > 5$ Myr, the excess fractions were $45\% \pm 14\%$, $8\% \pm 3\%$, and $4\% \pm 3\%$ of WTTSs, respectively. Furthermore, the mean ages of each evolutionary group of SEDs show a progressive trend. The robust means of the ages of **TNIR**, **TIRAC**, **T24**, and diskless objects are 0.6 ± 0.1 , 1.3 ± 0.3 , 1.5 ± 0.4 , and 4.1 ± 0.2 Myr, respectively. The robust mean ages of on-cloud and off-cloud WTTSs are 2.3 ± 0.2 and 4.2 ± 0.4 Myr, respectively. Of course, the individual ages have very large uncertainties and depend on which evolutionary model is used to estimate them (Cieza et al. 2007; Baraffe et al. 2009). However, the robust mean ages of each group of stars, especially their relative ages, are clearly less affected by these uncertainties.

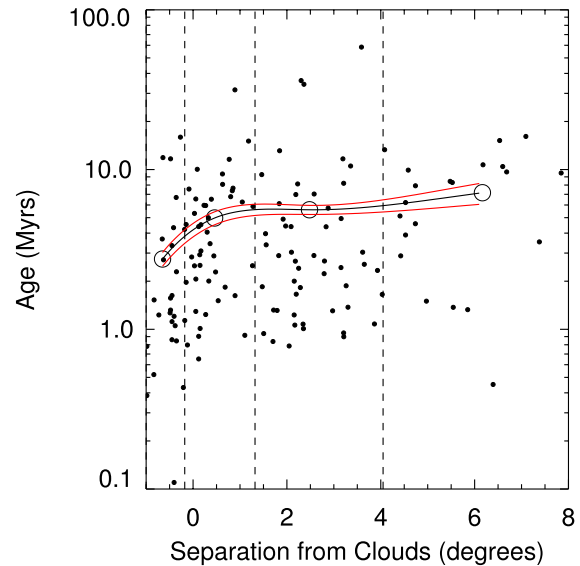

Figure 11. Ages obtained from the Siess et al. (2000) evolutionary tracks vs. the projected separations of the WTTSs from their parent cloud. The vertical dashed lines demarcate four cloud-separation bins within which mean ages are calculated. The solid black curve is a spline fit through these mean ages. The red curves indicate the 1σ errors in the mean ages. Thus, the mean age of objects increases noticeably with increasing separation from the cloud boundaries.

(A color version of this figure is available in the online journal.)

It is difficult to reason that the on-cloud and off-cloud WTTS populations, which are only 2 Myr apart but very well mixed in age, could have such different disk fractions (20% for on-cloud, 5% for off-cloud). The disk fraction would be much closer if the ages were really that mixed. We propose that the disk fractions are actually very sensitive to age, and the vast majority of disks evolve into the tenuous end phase of the primordial disk by roughly 3.5 Myr. It is quite plausible that the ages are actually a strong function of separation from the cloud, but that this relationship is confused by the uncertainty in the distances. We investigate this scenario in Figure 11, where we plot the measured ages versus the projected separations. We see that the mean ages in the four bins increase gradually with separation, and the errors in the means are small enough to make this trend significant. At projected cloud separations of -0.65 , 0.46 , 2.5 , and 6.2 deg, the mean ages are 2.75 ± 0.5 , 5 ± 0.75 , 5.6 ± 0.8 , and 7.2 ± 1.6 Myr. Of course, an age–separation relation is not expected to be strict as there many other factors involved in the spatial distribution of young stars.

4.3. Connection Between Disk Fraction and Multiplicity

Since even extremely young WTTSs have a measurably lower disk fraction than CTTSs, it has been conjectured that unseen stellar companions may be responsible for clearing the inner disks of WTTSs. The alternative explanations are that WTTSs are slightly older objects or that they resulted from very different initial conditions than CTTSs, which make them more susceptible to disk dissipation by photo-evaporation or tidal interaction, for example. Nevertheless, we look at published multiplicity studies on our objects, to see if binaries show measurably different disk fractions. Also of interest is whether binary systems halt disk accretion quickly. In other words, are WTTSs preferentially binaries?

The most comprehensive study to date on the effect of binarity on the disk excess rate is that of Cieza et al. (2009). They found that the IRAC excess fraction for binaries with separation less

Table 4
Average Properties of Different SED Object Types

Statistics	TNIR	TIRAC	T24	RJ
<i>N</i>	24	13	9	134
Mean age (Myr)	0.6 ± 0.1	1.3 ± 0.3	1.5 ± 0.4	4.1 ± 0.2
Mean f_{lum}	$7 \pm 0.7 \times 10^{-2}$	$3.7 \pm 0.7 \times 10^{-2}$	$1.7 \pm 0.5 \times 10^{-3}$	$< 5 \pm 1 \times 10^{-4}$

40 AU is $38\% \pm 6\%$, while it was $78\% \pm 7\%$ for systems with larger separation. However, their study pertains to inner hole clearing sizes of ~ 1 AU and somewhat younger objects, since their sample was composed of mostly on-cloud objects and they only dealt with the IRAC bands.

The multiplicity information on our sample comes from several kinds of companion surveys. Apart from the Cieza et al. (2009) compilation of speckle interferometry, radial velocity, lunar occultation, and adaptive optics surveys, we found other binarity information in the literature which are listed in Table 1. To summarize the disparate kinds of companion searches, these surveys can find or rule out the existence of a companion at two regimes. The spectroscopic surveys are sensitive to systems with periods of hundreds of days (roughly 1 AU separation) and the imaging surveys are sensitive to companions with roughly $0''.15$ separation (~ 20 AU). We count as binary all objects for which any kind of companion was found within $1''$. All objects which were unsuccessfully searched we consider single. Systems with widely separated companions (hundreds of AU) can easily harbor a disk around either component, as the companion only forces disk truncation to one third the total separation (Papaloizou & Pringle 1977).

In our sample of 33 CTTs, the ratio of the number of CTTs for which companions were found versus the total number searched is $9/19$ ($47\% \pm 16\%$). The same ratio for the WTTSs is $27/82$ ($33\% \pm 6\%$). Despite the small number of sources, there is no evidence in these data that WTTSs are more likely than CTTs to be binaries.

Now, 7 of the 31 ($23\% \pm 4\%$) binary WTTSs exhibit IR excess, whereas 6 of 55 ($11\% \pm 4\%$) purportedly single WTTSs show IR excess. Since binaries stars have two chances to have a disk, the disk fraction of an individual star in a binary system is $DF_i = 1 - \sqrt{1 - DF_s}$, where DF_s is the disk fraction of the system, which is all we can measure for unresolved pair (Cieza et al. 2009). Thus, our individual WTTS disk fraction turns out be $12\% \pm 3\%$, virtually the same as the single star disk fraction. However, our WTTS binaries include systems with wide separations (~ 100 AU) which are expected to be much more conducive to disks. We also included old WTTSs which are likely to have lower disk fractions. A combination of population contamination and biases is probably masking the effect of binarity on disk lifetimes as seen by Cieza et al. (2009).

When we try to divide our sample into the two groups chosen by Cieza et al. (2009), we find that we have very small statistics. In the first WTTS group we place all the spectroscopic binaries, and the detected binaries with separation less than $0''.2$ (roughly $\rho < 40$ AU), while in the second WTTS group, we put all the wider binaries. For the tight binaries, we get an excess fraction of $4/17$ ($24\% \pm 12\%$), while the wide binary disk fraction is $3/14$ ($21\% \pm 12\%$). Thus, the results are inconclusive. If a study complementary to the Cieza et al. (2009) work were to be done for older WTTSs and for disks detected as MIPS excess, we would need a much larger sample of off-cloud binaries.

Recent studies which have compared disk fractions in single and binary systems show how different results are obtained from

different samples. Pascucci et al. (2008) found no evidence of the effect of binarity on disk emission in a carefully selected medium-separation sample ($\rho \sim 14\text{--}420$ AU) in Taurus (age $\sim 1\text{--}3$ yr). However, for the late-type stars in the 8 Myr old η Chamaeleontis cluster, Bouwman et al. (2006) found that 8 of 9 single stars and 1 of 6 binary systems ($\rho < 20$ AU) had a disk. Although these results seem to show that small separation systems affect disk lifetimes while large separation systems do not, the two samples have different ages. Differing ages, separations, masses, and viewing angles of the systems under study, which are often quite uncertain, can easily confuse the true effect of binarity in small samples. Pott et al. (2010) showed that there are no stellar companions in five of the most clearly classifiable transition disks, in the region between ~ 0.35 and 4 AU from the stars. Thus, if one has to invoke companions as an explanation for the disk clearings, they would have to be substellar.

4.4. Physical Interpretation of SEDs

The objects with SED types **TNIR**, **TIRAC**, **T24**, and **RJ** had mean ages of 0.6 ± 0.1 , 1.3 ± 0.3 , 1.5 ± 0.4 , and 4.1 ± 0.2 Myr and mean disk fractional luminosities of these groups were $(7 \pm 0.7) \times 10^{-2}$, $(3.7 \pm 0.7) \times 10^{-2}$, $(1.7 \pm 0.5) \times 10^{-3}$, $(3.8 \pm 1) \times 10^{-3}$, and lastly a mean upper limit of $(5 \pm 1) \times 10^{-4}$, respectively. Thus, in terms of age and disk fractional luminosity these statistics strongly suggest an evolutionary trend through these SED types. The average properties of the objects of different SED types are shown in Table 4.

The **T24** objects have comparable f_{lum} to known resolved debris disks, and are probably optically thin disks with inner clearings no larger than the terrestrial planet regions. About $6\% \pm 4\%$ of accreting stars (CTTs) have SEDs of this type. The **TIRAC** objects are just a little younger, with smaller inner clearings and larger fractional luminosities which are just above the informal debris disk demarcation line at $f_{\text{lum}} = 1 \times 10^{-2}$. About $24\% \pm 9\%$ of accreting stars have SEDs of this type. The **TNIR** disks fall into the category of traditional optically thick disks ($61\% \pm 14\%$ of CTTs fall into this category). It should be noted that although we have designated the **RJ** objects as diskless they might easily have debris disk of fractional luminosity comparable to the β Pictoris disk in regions analogous to their Kuiper belts.

In Figure 12, we examine the SEDs of these groups of objects. The shapes of the SEDs of most of the WTTS **TNIR** and **TIRAC** objects indicate a depleted region or a gap in the disks. The excess in the IRAC bands definitely indicate an inner disk ($r \sim 1$ AU), but the emission coming from the middle disk ($r \sim 40$ AU) is obviously much more robust as seen in the MIPS bands. Thus, it seems that the middle disk survives the inner disk. Cieza et al. (2008) found that objects with low $24 \mu\text{m}$ excesses are not detected in the submillimeter, just as we found that these objects are also not detected at $70 \mu\text{m}$. They understood this to indicate that the inner disk only dissipates after the outer disk has been significantly depleted of mass.

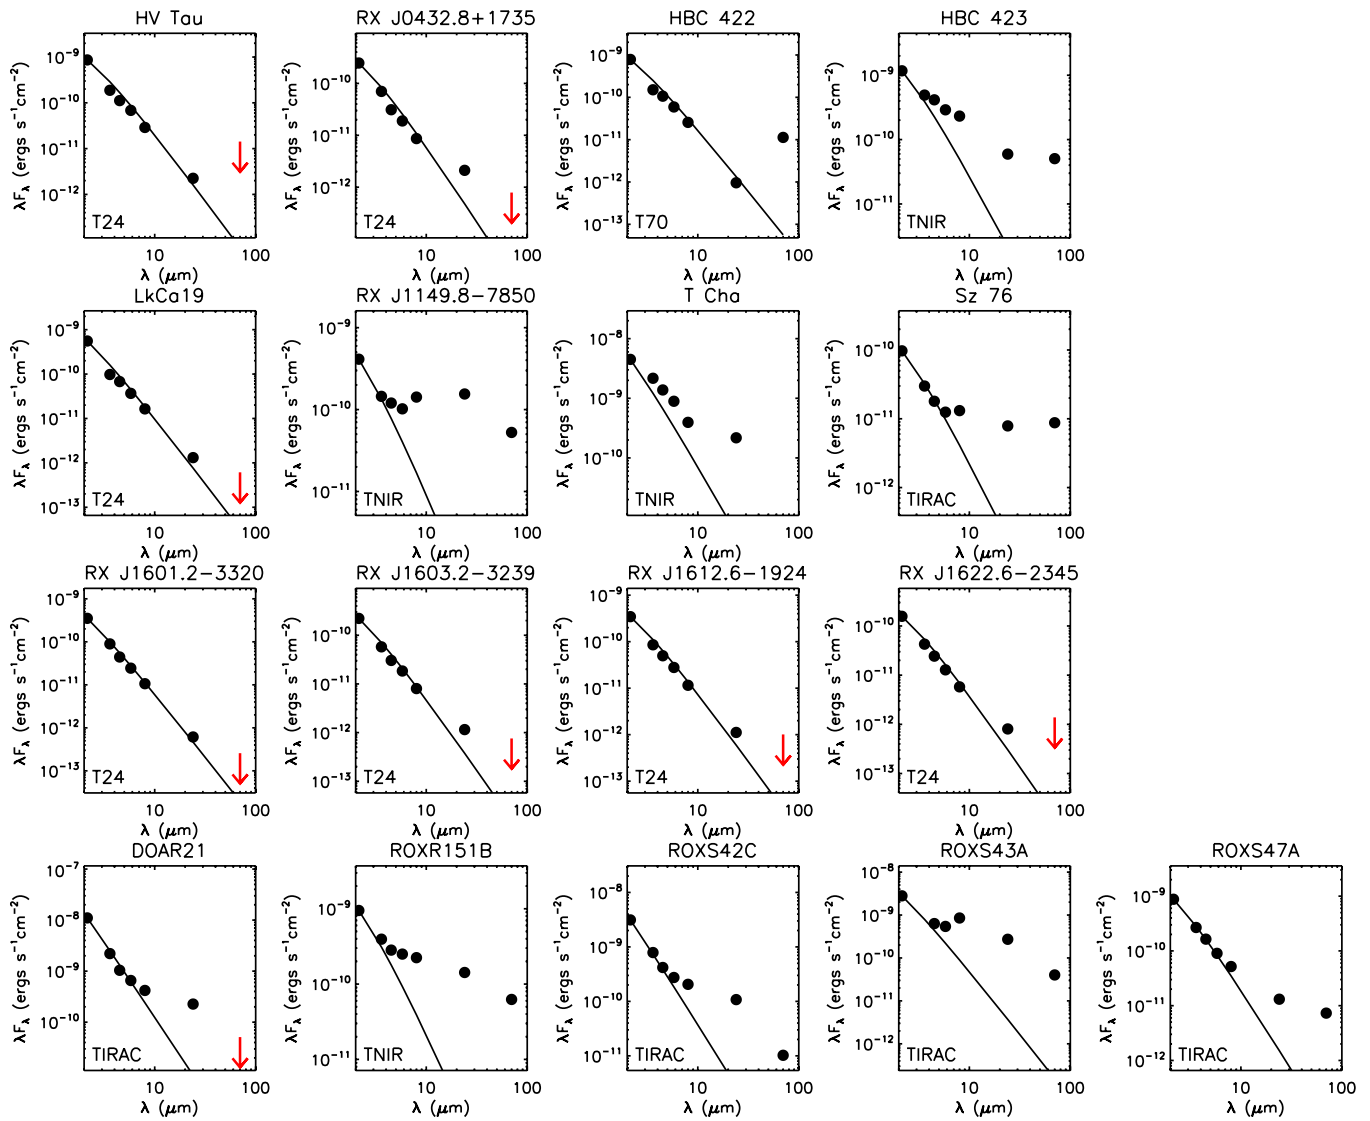

Figure 12. SEDs of the WTTs with excess. The solid line represents the Planck function of the appropriate temperature normalized to the extinction corrected K -band flux. The red arrows are 3σ upper limits to the $70\ \mu\text{m}$ flux density. The plots are labeled with their disk “turn-on” classifications which are also given in Table 1. (A color version of this figure is available in the online journal.)

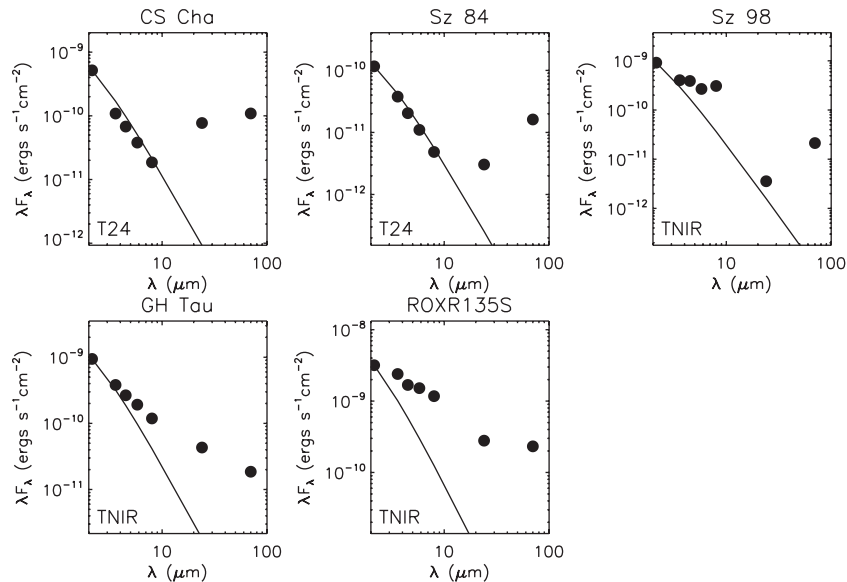

Figure 13. SEDs of the interesting CTTs with excess (see Section 4.5). The solid line represents the Planck function of the appropriate temperature normalized to the extinction corrected K -band flux. The plots are also labeled with their disk “turn-on” classifications which are also given in Table 1.

4.5. New Interesting Objects

Accreting disks with large holes. CS Cha and Sz 84 fall into this category of objects. Was it grain growth that cleared out the dust? Are they accreting because there is no inner companion to stop the gas flow or are they accreting despite an inner companion? They show no excess in the IRAC bands but show robust excesses at 24 and 70 μm (Figure 13). They both have disks with fractional luminosities of ~ 0.1 , and they are both solid accretors with $\text{FW.1H}(H\alpha)$ of $\sim 400 \text{ km s}^{-1}$. CS Cha has a companion (mass $\sim 0.1 M_{\odot}$; Guenther et al. 2007) with a 2435 day period ($\rho \sim 3 \text{ AU}$), while Sz 84 was not targeted in a high-resolution search. The CS Cha SED from earlier *Spitzer* photometry and IRS spectra has been modeled as disk emission in detail to predict a 43 AU inner hole (Espaillat et al. 2007). Given the IRAC and MIPS photometry we obtained, both disks can be modeled with holes at small as 2 AU.

WTTSs with robust disks. There are four stars of this type: HBC 423, RX J1149.8-7850, T Cha, and ROXR1 51b (Figure 12). All these show robust emission at 24 and 70 μm . The IRAC fluxes of these objects clearly show very depleted inner regions. These objects represent the youngest non-accreting or weakly accreting disks. Why has accretion weakened? How is the disk maintained?

Zodiacal dust disks. The CTTSs Sz 98 exhibits excess emission which basically has a Rayleigh–Jeans slope beyond 6 μm and peaks near the IRAC2 band (Figure 13). This indicates a warm contributor to the excess ($T \sim 600 \text{ K}$), such as would be expected from a dust ring confined to within 0.5 AU of the star. The 8 μm flux is actually anomalously high and inconsistent with the 24 μm detection unless it results from some line emission (e.g., from silicates or PAHs). Sz 98 is of spectral type K8 and is known to be a spectroscopic single, though it may have a companion at separations between 0'.1 and 1'.

Intermediate separation binaries with robust disks. Binaries at a few tens of AU separations are supposed to make the least conducive environments for massive circumstellar disks. If their physical separations are a few tens of AU, then these objects are interesting because they provide test cases to current theories of planet formation in binary systems (Quintana & Lissauer 2006; Marzari & Barbieri 2007). Binary systems with projected separations between 0'.1 and 0'.4 ($\rho \sim 15$ to 60 AU) with fractional disk luminosities above 0.01 are WTTSs, HBC 423 (TNIR), and ROXS 42C (TIRAC; Figure 12) and CTTSs, GH Tau (TNIR), and ROXR1 135S (TNIR; Figure 13). All of these show robust 70 μm emission which is either rising or roughly flat with respect to their 24 μm fluxes. The SEDs show no signs of gaps in the disk. These systems may thus be pointing to non-disruptive mechanisms for companion and disk interactions that we may not have foreseen.

5. CONCLUSIONS

We have presented the final results of the first large scale far infrared disk survey of WTTSs. The WTTS stars in the young star-forming regions within 200 pc (Chamaeleon, Lupus, Ophiuchus and Taurus) were probed for infrared excess from 3.6 to 70 μm , in an effort to study the evolutionary status of their disks. We showed that overall 11% of WTTSs have a disk brighter than the β Pictoris debris disk ($f_{\text{lum}} = 2 \times 10^{-3}$). However, the disk fraction for WTTSs within 1° of the nearest cloud was 19%, while the disk fraction for WTTSs farther away was 5%. As we move from on-cloud to off-cloud, stars get gradually older and have progressively lower disk fractions.

Of the fraction detected with disks, objects were classified into five groups according to disk "turn-on" wavelengths **TNIR**, **TIRAC**, **T24**, **T70**, and **RJ**. These groups showed easily identifiable trends in terms of age and fractional luminosity. They suggest a sequential transition of accreting optically thick disks into passive optically thick disks into optically thin disks and eventually into apparently diskless systems with $f_{\text{lum}} < 5 \times 10^{-4}$ over roughly 4 Myr. Even though the timescales for individual objects may vary wildly, objects with more evolved SEDs on average tend to be older. The incidence rate of β Pictoris-like debris disks for both the on and off-cloud WTTSs may be much higher than the disk rate reported here, since fainter disks are just beyond the capability of our survey.

The mean ages of the CTTSs, and on-cloud and off-cloud WTTSs were also distinguishable from each other because of large statistics in each of these groups. The on-cloud WTTSs seem to be measurably older than CTTSs (mean age $\sim 0.8 \pm 0.1 \text{ Myr}$), but they still constitute a very young population (mean age $\sim 2.3 \pm 0.3 \text{ Myr}$). One reason why previous studies have not reported this difference is perhaps because even our on-cloud WTTSs include some older stars, due to a bias in the *ROSAT* selection. However, the mean age of WTTSs with disks ($1.3 \pm 0.3 \text{ Myr}$) is basically the same as that of the CTTSs, which indicates that systems with disks are a younger group. However, for the off-cloud objects, we may attach a lower age bound of $\sim 3 \text{ Myr}$, while the upper bound remains somewhere around 100 Myr deduced from X-ray and lithium detections. Our analysis, however, suggested that the off-cloud WTTS apparent luminosities are consistent with an age of less than 10 Myr. Thus, they are indeed predominantly an older population as previously surmised (Padgett et al. 2006; Cieza et al. 2007), and the nature of this still arguably young (3–10 Myr old) population remains a very interesting question.

The analysis of the effect of binarity on disk fractions was inconclusive because of the small number of binaries in our sample and the small excess rates we are dealing with. We are thus not able to complement or test the results of Cieza et al. (2009). An interesting study would be to look at the MIPS disk fractions of a sample of off-cloud binary WTTSs numbering in the hundreds, to get beyond the diluting effects of the differing viewing angles, masses and ages of the systems. Such a study would explain the effect of binarity on outer disks in relatively older systems.

When looking at the disk fraction as a function of spectral type, we restricted ourselves only to on-cloud objects, in order to consider only the young objects. The excess rate for spectral types G0 through K5 was $10\% \pm 7\%$ while that for later spectral types was $19\% \pm 7\%$. Also it seems that the less evolved SED types are concentrated in the later spectral types.

We also find that, in a large number of cases, nebulosity or confusion with nearby YSOs can result in false detections of 70 μm excess around WTTSs. Such problems can be avoided by careful comparisons of the emission centers at 70 μm and IRAC bands and requiring the shapes of emission to be point source-like. However, since false positives were found to be as frequent as bona fide detections, it seems that the environs of WTTSs within $\sim 20''$ are frequently occupied by young objects or cloud material. Higher resolution far-infrared and submillimeter imaging of the neighboring cold cloud material may reveal heretofore unknown ways in which the WTTS environs affect their disks.

Support for this work, which is part of the *Spitzer* Legacy Science Program, was provided by NASA through contracts

1224608, 1230782, and 1230799 issued by the Jet Propulsion Laboratory, California Institute of Technology under NASA contract 1407. This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center funded by NASA and the National Science Foundation.
